

Numerical Study of Traveling Wave Solutions to 2D Boussinesq Equation

K. Angelow, N. Kolkovska

ABSTRACT. The aim of this paper is to evaluate stationary propagating wave solutions to the two dimensional Boussinesq equation. To solve the resulting nonlinear fourth order elliptic problem we use a combination of high order finite difference schemes, an iterative procedure and new asymptotic boundary conditions. A number of numerical results are obtained for the validation of the method and for dependence of the wave's shape on the velocity c and dispersion parameters. We give also a comparison with the numerical results and best-fit formulae given in [8, 9].

1. Introduction.

In this paper we consider the two dimensional Boussinesq Equation (BE)

$$(1) \quad u_{tt} - \Delta u - \beta_1 \Delta u_{tt} + \beta_2 \Delta^2 u + \Delta f(u) = 0 \quad \text{for } (x, y) \in \mathbb{R}^2, t \in \mathbb{R}^+,$$

Key words: two dimensional Boussinesq equation, traveling wave solutions (TWS), high order finite difference schemes, asymptotic boundary conditions

*This work was supported by the Institute of Mathematics and Informatics, Bulgarian Academy of Sciences.

$$\begin{aligned}
& u(x, y, 0) = u_0(x, y), \quad u_t(x, y, 0) = u_1(x, y) \quad \text{for } (x, y) \in \mathbb{R}^2, \\
(2) \quad & u(x, y) \rightarrow 0, \Delta u(x, y) \rightarrow 0, \quad \text{for } \sqrt{x^2 + y^2} \rightarrow \infty,
\end{aligned}$$

where $f(u) = \alpha u^2$, $\alpha > 0$, $\beta_1 > 0$, $\beta_2 > 0$ are dispersion parameters, and Δ is the Laplace operator. The BE is famous with the approximation of shallow water waves or also weakly non-linear long waves. It is often used for simulation of various physical processes e.g. turbulence in fluid mechanics, vibrations in acoustics and, etc. A derivation of the BE from the original Boussinesq system can be found in [7].

The goal of the article is to seek for solutions to (1) of the type $u(x, y, t) = U(x, y - ct)$, which are stationary solitary waves (SSW) traveling in y direction with velocity c . In a forthcoming paper the SSW will be applied as initial condition (IC) of the hyperbolic BE (1), (2). Thus it is useful to have accurate, flexible and robust IC in order to test various scenarios with two or more traveling waves colliding with each other.

The SSWs to (1) are computed by a Galerkin spectral method in [3, 4]. In [9] a second order finite difference scheme is used, while in [8] the perturbation series method with respect to the small parameter c is applied. Moreover in [8] the resulting numerical solution is approximated by best-fit formulae. These exact expressions are used further as initial conditions in numerical simulations of the unsteady BE (1)-(2), see [2, 10]. It is shown in these papers, that for velocities $c < 0.3$ the resulting SSW disperse in the form of ring wave expanding to infinity or blow up after some period in time. Thus the traveling wave solutions of the hyperbolic equation (1) are very fragile, i.e. the wave easily blow up or fall apart with time. The relationship between the dispersion and nonlinearity in (1) is very sensitive and the balance between them is easily destroyed. Moreover it is well known that in the one dimensional case the solitary waves are unstable for small wave speeds c while they are stable in form for velocities c close to 1.

Having in mind these observations, we focus in this paper on the more accurate evaluation of SSW U to (1), especially for velocities $c > 0.7$, since it is fundamental for the construction of initial data of the unsteady BE (1).

Note that the stationary solitary waves $U(x, y - ct) = u(x, y, t)$ satisfy the following nonlinear fourth order elliptic equation

$$(3) \quad c^2(E - \beta_1 \Delta)U_{yy} = \Delta U - \beta_2 \Delta^2 U - \Delta f(U),$$

where E is the identity operator.

The evaluation of the solution to (3) described here follows the steps presented in [9], but new modifications are introduced to meet the higher requirements reported above.

First, for the numerical solution of (3) we choose to apply an uniform grid with equal step size $h_x = h_y = h$ in the computational domain Ω_h instead of a nonuniform grid. The reason for this is that the computed solutions to (3) will be used as initial conditions in the hyperbolic problem (1) and these solutions will travel in time, thus we have to have more mesh points not only close to the peak of the waves, but everywhere in the computational domain.

In order to increase the precision of the numerical method, we apply finite difference schemes (FDS) with local approximation of forth $O(h^4)$ and sixth $O(h^6)$ order, i.e. we approximate second order spatial derivatives with high order finite differences. These FDS allow one to evaluate the numerical solution with high accuracy on relatively coarse grid.

A new boundary condition on the computational boundary is also used [5], together with uniform grid and local approximation order of $O(h^4)$ and $O(h^6)$. The numerical solution of the fourth order elliptic problem (3) is replaced with an iterative procedure, which involves solution of an appropriate parabolic type problem at every iteration step. At the end of each iteration procedure the residual defined in (12) of the discrete equation, approximating (4) is of order 10^{-5} , 10^{-6} and the distance between two consecutive iterations of the solution is of order 10^{-7} , which is much smaller than the discretization step size h .

In the last section we examine the solution shape and the dependence of the solution on the input parameters - the velocity c and the relative dispersion $\beta = \beta_1/\beta_2$. It is shown that these qualitative properties of the numerical solution are very similar to those given for the numerical solution in [8, 9]. The results here are compared with the best-fit formulas given in [8], which approximate the numerical solution in [8, 9]. The analysis shows that these best-fit formulas do not satisfy the equations in the neighborhood of the origin in the classical sense because their fourth order derivatives have singularities at the origin. The difference (measured in the maximal norm and in L_2 norms) between our numerical solution and the corresponding best-fit formulae is also high, especially for large velocities c .

The paper is organized as follows. In Section 2 we formulate the problem. The numerical method is given in Section 3 and validated in Section 4. Various numerical experiments and a comparison with results in [8, 9] are reported in Section 5.

2. General Formulation. By the change of variables $x = \sqrt{\beta_1}\bar{x}$, $y = \sqrt{\beta_1}\bar{y}$, $U(x, y) = v(\bar{x}, \bar{y})$ equation (3) is rewritten in the form

$$(4) \quad c^2\beta(E - \Delta)v_{\bar{y}\bar{y}} = \beta\Delta v - \Delta^2 v - \beta\Delta f(v)$$

with $\beta = \beta_1/\beta_2$. The solution v to (4) and its derivatives tend to zero as $|x^2 + y^2| \rightarrow \infty$. In the following we use notations x, y instead of \bar{x}, \bar{y} .

If the condition $c^2 < \min(1/\beta, 1)$ holds then (4) is an elliptic equation of fourth order and the linear second order derivatives in (4) form a second order elliptic equation. In this paper we consider velocities c which fulfill this inequality.

Problem (4) can be rewritten as a system of two elliptic equations of second order in different ways. We expect that the derivatives v_{xx} in x direction will be smaller than the derivative v_{yy} in y direction (since the solution travels in y direction). Therefore the equality $v_{yy} = \Delta v - v_{xx}$ is substituted in (4) and, after introducing an auxiliary function w , we obtain the equivalent to (4) system

$$(5) \quad -(1 - c^2\beta)\Delta v + \beta(1 - c^2)v + \alpha\beta v^2 = w,$$

$$(6) \quad -\Delta w = c^2\beta(E - \Delta)v_{xx}.$$

We seek non-trivial solutions to (5)-(6). To avoid the trivial solution we proceed as in [9]: we fix the value of the solution v at the point $(0, 0)$, $v(0, 0) = \theta$ and introduce new functions: $\hat{v} = v/\theta$ and $\hat{w} = w/\theta$. Thus $\hat{v}(0, 0) = 1$ and

$$(7) \quad \begin{aligned} -(1 - c^2\beta)\Delta\hat{v} + \beta(1 - c^2)\hat{v} + \alpha\beta\theta\hat{v}^2 &= \hat{w}, \\ -\Delta\hat{w} &= c^2\beta(E - \Delta)\hat{v}_{xx}. \end{aligned}$$

The value of θ is found from the equation

$$(8) \quad \theta = \frac{(1 - c^2\beta)\Delta\hat{v} - \beta(1 - c^2)\hat{v} + \hat{w}}{\alpha\beta} \Big|_{x=0, y=0}.$$

In order to evaluate numerically the solution to (7) we introduce artificial time, add false time derivatives and get

$$(9) \quad \begin{aligned} \frac{\partial\hat{v}}{\partial t} - (1 - c^2\beta)\Delta\hat{v} + \beta(1 - c^2)\hat{v} + \alpha\beta\theta\hat{v}^2 &= \hat{w}, \\ \frac{\partial\hat{w}}{\partial t} - \Delta\hat{w} &= c^2\beta(E - \Delta)\hat{v}_{xx}. \end{aligned}$$

Thus the solution to the steady coupled elliptic system (7) is replaced by solving the pertinent transient equations (9) until their solutions \widehat{v} and \widehat{w} cease to change significantly in time.

3. Numerical Method. First we replace the unbounded domain by a sufficiently large computational domain Ω . Due to the obvious symmetry of the problem, we can look for the solution only in the first quadrant $\Omega = [0, L_x] \times [0, L_y]$. Then a uniform grid Ω_h is defined in the following way

$$\Omega_h = \{(x_i, y_j) : x_i = ih, y_j = jh, i = 0, \dots, N_x, j = 0, \dots, N_y\},$$

where the discretization step h satisfies $h = L_x/N_x = L_y/N_y$. In the implementation of the numerical method the step size τ may vary according to the residual of the computed solution. This is a crucial point because it permits to automatize the control of the error. The value of the function v at mesh point x_i, y_j, t_k is denoted by $v_{i,j}^k$.

We discretize the spatial derivatives in (9) using centered finite differences and extending the stencil:

$$(10) \quad v_{\widehat{xx},p}(x) := \frac{1}{h^2} \sum_{i=-p/2}^{p/2} d_i v(x + ih),$$

Here p is equal to 2, 4 or 6. The weights d_i taken from [11] are 1, -2, 1 for $p = 2$, $-\frac{1}{12}, \frac{4}{3}, -\frac{5}{2}, \frac{4}{3}, -\frac{1}{12}$ for $p = 4$ and $\frac{1}{90}, -\frac{3}{20}, \frac{3}{2}, -\frac{49}{18}, \frac{3}{2}, -\frac{3}{20}, \frac{1}{90}$ for $p = 6$. The approximation error of formulae (10) is $O(h^p)$. Replacing the Laplace operator in (9) by the discrete Laplacian

$$\Delta_{h,p} v_{i,j} := (v_{i,j})_{\widehat{xx},p} + (v_{i,j})_{\widehat{yy},p}$$

we obtain finite difference schemes with high order of approximation $O(h^4)$ for $p = 4$ and $O(h^6)$ for $p = 6$. The application of FDS with high order of approximation leads to a high rate of convergence of the method for sufficiently smooth solutions. In this way more accurate solutions can be produced on a coarse grid.

Symmetry conditions are used to impose the values of the discrete Laplacian at mesh points close to $(0, y)$, and $(x, 0)$. Near the computational boundaries $(x, y) : x = L_x$ and $(x, y) : y = L_y$ we do not change the stencil. The discrete Laplacian is defined there by using the values of the discrete solution given in (13), (14) below at points outside the computational domain.

The Euler explicit rule is applied for approximation of time derivatives. The nonlinear terms in (4) are computed on time level t^k . Thus, the numerical solutions at time level t^{k+1} are evaluated directly by the values of the numerical solution at time level t^k :

$$(11) \quad \begin{aligned} \frac{\widehat{v}_{i,j}^{k+1} - \widehat{v}_{i,j}^k}{\tau} - (1 - c^2\beta)\Delta_{h,p}\widehat{v}_{i,j}^k + \beta(1 - c^2)\widehat{v}_{i,j}^k + \alpha\beta\theta(\widehat{v}_{i,j}^k)^2 &= \widehat{w}_{i,j}^k, \\ \frac{\widehat{w}_{i,j}^{k+1} - \widehat{w}_{i,j}^k}{\tau} - \Delta_{h,p}\widehat{w}_{i,j}^k &= c^2\beta(E - \Delta_{h,p})\widehat{v}_{i,j,\widehat{x}x,p}^k. \end{aligned}$$

This method for solving equations (7) can be considered also as “the simple iteration method” for solving linear and nonlinear equations (see [12]). Last but not least, in order to start the procedure we need initial values for functions \widehat{v} , \widehat{w} . These initial values are taken from the formulae in [8].

0.0.1 3.1 Time Step Control.

It is possible to use varying time step τ to optimize and speed up the algorithm. When the time step becomes too big the solution starts to diverge and becomes jagged. Fortunately these signs appear first in the residual R , i.e. it starts to grow and jag simultaneously while the solution is still fine. When this happens, an arbitrary cross-section of it looks like a discrete function which alternates positive with negative values on the grid. This is a clear sign that the time step has to be lowered, otherwise it is increased. Changing the artificial time is done automatically at each iteration by a factor $f_\tau\tau =: \tau_{new}$, where $f_\tau \in (0.72, 1.015)$.

The residual $R_{i,j}^k$ of the discrete approximation to (4) at the mesh point (x_i, y_j, t^k) is defined as:

$$(12) \quad R_{i,j}^k := c^2\beta(\widehat{v}_{i,j}^k)_{\widehat{y}y,p} + \Delta_{h,p}(-\beta\widehat{v}_{i,j}^k - c^2\beta(\widehat{v}_{i,j}^k)_{\widehat{y}y,p} + \Delta_{h,p}\widehat{v}_{i,j}^k + \alpha\beta\theta(\widehat{v}_{i,j}^k)^2).$$

0.0.2 3.2 Asymptotic conditions on the boundaries $x = L_x$ and $y = L_y$.

The behavior of the solutions v and w as $r = \sqrt{x^2 + y^2} \rightarrow \infty$ is studied in details in [5, 8, 9]. The following formulas

$$(13) \quad \bar{v}(x, y) = \mu \frac{((1 - c^2)x^2 - y^2)}{((1 - c^2)x^2 + y^2)^2}$$

and

$$(14) \quad \bar{w}(x, y) = \tilde{\mu}(1 - c^2) \frac{((1 - c^2)x^2 - y^2)}{((1 - c^2)x^2 + y^2)^2}$$

given in [5] are found to describe very well the unknown functions v and w on the computational boundary $\partial\Omega_h$.

In order to resolve the boundary functions (13) and (14) completely one needs μ and $\tilde{\mu}$ parameters. We obtain them iteratively, at each time level of (11), by the following minimization procedure. For given solutions $v_{i,j}^k$ and $w_{i,j}^k$ at time level t^k we choose μ and $\tilde{\mu}$ as minimizers of

$$(15) \quad \mu = \min_{\mu > 0} \|\bar{v}(x_i, y_j) - \hat{v}_{i,j}^k\|_{L_2, \hat{\Omega}}, \quad \tilde{\mu} = \min_{\mu > 0} \|\bar{w}(x_i, y_j) - \hat{w}_{i,j}^k\|_{L_2, \hat{\Omega}}.$$

0.0.3 3.3 Stop Criteria.

Usually the calculations of \hat{v}^{k+1} by equations (11) are terminated if

$$\max_{i,j} |\hat{v}_{i,j}^{k+1} - \hat{v}_{i,j}^k| < \epsilon \max_{i,j} |\hat{v}_{i,j}^k|,$$

where ϵ is a prescribed accuracy. But the solution decays as $\sim 1/r^2$ for $r \rightarrow \infty$, $r = \sqrt{x^2 + y^2}$. Thus for large x and y , the following expressions

$$(16) \quad x^2 U(x, 0, t) \sim c_x \quad \text{and} \quad y^2 U(0, y, t) \sim c_y$$

have asymptotics of constant functions c_x and c_y respectively. There exist start points x_s and y_s for which the asymptotic conditions are valid inside the intervals $[x_s, x_{end}]$ and $[y_s, y_{end}]$. Furthermore, (16) are also valid on intervals $[x_m, x_{end}]$ and $[y_m, y_{end}]$, where x_m and y_m are the mid-points i.e. $x_m = (x_s + x_{end})/2$ and $y_m = (y_s + y_{end})/2$.

At each k^{th} successful iteration $k \in N$, the two expressions in (16) are approximated by constant functions (zero order polynomial) $c_x(x_i) = c_x$ and $c_y(y_i) = c_y$ with $x_i \in [x_m, x_{end}]$ and $y_i \in [y_m, y_{end}]$ respectively.

In between each k iterations, the approximations are evaluated and compared with each other i.e., if the linear fits c_x and c_y

Figure 1: Stop Criteria Intervals

$$(17) \quad |c_x^n - c_x^{(n-k)}| < \epsilon \quad \text{and} \quad |c_y^n - c_y^{(n-k)}| < \epsilon$$

cease to change significantly between k iterations then the solution has converged. Here the superscript n is the current iteration number and c_x^n means the value of c_x at the n -th iteration.

0.0.4 3.4 Basic Algorithm Steps.

The following are the most important mile-stones during the implementation of the algorithm.

- 1) Resolve proper initial condition (v^0, w^0) on the grid Ω_h . Set parameters ϵ and τ .
- 2) Suppose (v^k, w^k) are known.
 - 2.1) Find current θ_k from the discrete approximation of (8);
 - 2.2) Evaluate the solution on the computational boundary;
 - 2.3) Evaluate $\Delta_{h,p}\hat{v}^k$ and $\Delta_{h,p}\hat{w}^k$;
 - 2.4) Calculate $(\hat{v}^{k+1}, \hat{w}^{k+1})$ on the time level t^{k+1} by the Euler explicit scheme (11);
 - 2.5) Calculate the residual $R_{i,j}^{k+1}$ from (12) and check the stop condition (17).
 - 2.6) Control the time step size τ . Set $t^{k+1} = t^k + \tau$.
- 3) Continue steps 2.1) -2.6) with the next time level t^{k+1} till condition (17) is satisfied.

4. Validation.

In this section we give several numerical results concerning the verification of the presented numerical method. We use FDS with different approximation errors and several sets of parameters c, α, β , which are shown on each table.

In this series of tests we evaluate the numerical solution of (9) using FDS with approximation errors $O(h^2)$, $O(h^4)$, $O(h^6)$ and parameters $\alpha = 1$, $\beta = 3$, $\epsilon = 10e - 5$, $L_x = 30$, $L_y = 30$. The initial conditions for the artificial parabolic problem (11) are taken from [8]. Using the values of numerical solution on three nested meshes we compute the numerical rate of convergence (Conv. Rate) in L_2 and L_∞ mesh norms by Runge method as $(\log E_1 - \log E_2)/\log 2$. Here $v_{[h]}$, $v_{[h/2]}$ and $v_{[h/4]}$ represent the numerical solution over three nested meshes and $E_1 = \|v_{[h]} - v_{[h/2]}\|$, $E_2 = \|v_{[h/2]} - v_{[h/4]}\|$. Table 1 contains the errors in L_2 and L_∞ norms and the corresponding numerical rate of convergence for the numerical solutions obtained by FDS with second, fourth and sixth order of approximation and velocities $c = 0.1$ or $c = 0.45$. We observe that the experimental rate of convergence approximates well the approximation error of the difference schemes- the FDS are of almost the same order of convergence as the order of approximation. An additional observation is that for the same step size h the schemes with higher

Table 1: Convergence test for FDS with different approximation errors ($O(h^2)$, $O(h^4)$ and $O(h^6)$). Errors E_i are measured in L_2 and L_∞ norms

order of approximation ($O(h^4)$, $O(h^6)$) lead to a more precise solution than the scheme with $O(h^2)$ approximation error.

5. Results.

In this section we apply the presented numerical method to study the characteristic properties of the obtained numerical solution. Many parametric dependencies of the numerical solution, discovered in [8, 9], such as dependence of the solution's shape on the velocity c and on the relative dispersion parameter β , are confirmed here once again. We also compare the best-fit formulae, built up in [8], with the numerical solution developed here. Such comparison is still missing in the literature. Recall that the best-fit formulae are used as initial data for our algorithm.

Figure 2: 2D and 3D profiles of the numerical solution u to (8) and (9)

0.0.5 5.1 Solution residual.

On the left picture in Figure 3 we present the residual (12), saved on the last time level of the numerical scheme (11), for $\beta = 5$ and $c = 0.3$, while the residual, evaluated for problem with $\beta = 1$, $c = 0.9$, is demonstrated on the right part of Figure 3. Here $\epsilon = 10e - 6$ and the FDS is of 6th order of approximation. In these cases the difference between the last two iterations is $3.7749e - 007$ for the first data set and $1.2726e - 007$ for the second data set. These results show that the equation (4) is satisfied numerically with high accuracy. Note that similar results about the residual for the numerical scheme in [9] are not reported there. Concerning the best-fit formulae from [8] – it is obvious to conclude from these formulae that the third, fourth and so on derivatives of the best-fit solution are unbounded in the neighborhood of the point $(0, 0)$. Thus the residual, which

Figure 3: Residual at the last step of iteration process (11)

includes fourth order derivatives of the solution, could not be considered and evaluated in the classical sense. Therefore the equation (4) is not satisfied in the neighborhood of the origin by the best-fit formulae from [8]!

Table 2: Errors in L_2 and L_∞ norms and convergence rate for fourth order discrete derivative evaluated by FDS with $O(h^2)$ and $O(h^6)$ approximation errors

0.0.6 5.2 Solution derivatives.

We have mentioned already that the best-fit formulae from [8] have singularities near the origin. Now we demonstrate that the discrete fourth order derivatives of the numerical solution converge numerically as the step size h goes to zero. We apply the Runge test, evaluating the discrete fourth order derivative $\widehat{v_{xxxx}}$ of the solution on three nested meshes with step sizes $h, h/2, h/4$ (see Section (0.0.4)). The results are demonstrated on Table 2. We conclude that the discrete derivative $\widehat{v_{xxxx}}$ is bounded and converges numerically for $h \rightarrow 0$. The tests for the other fourth order derivatives are similar to the derivative v_{xxxx} and we do not present them here.

0.0.7 5.3 Solution shape.

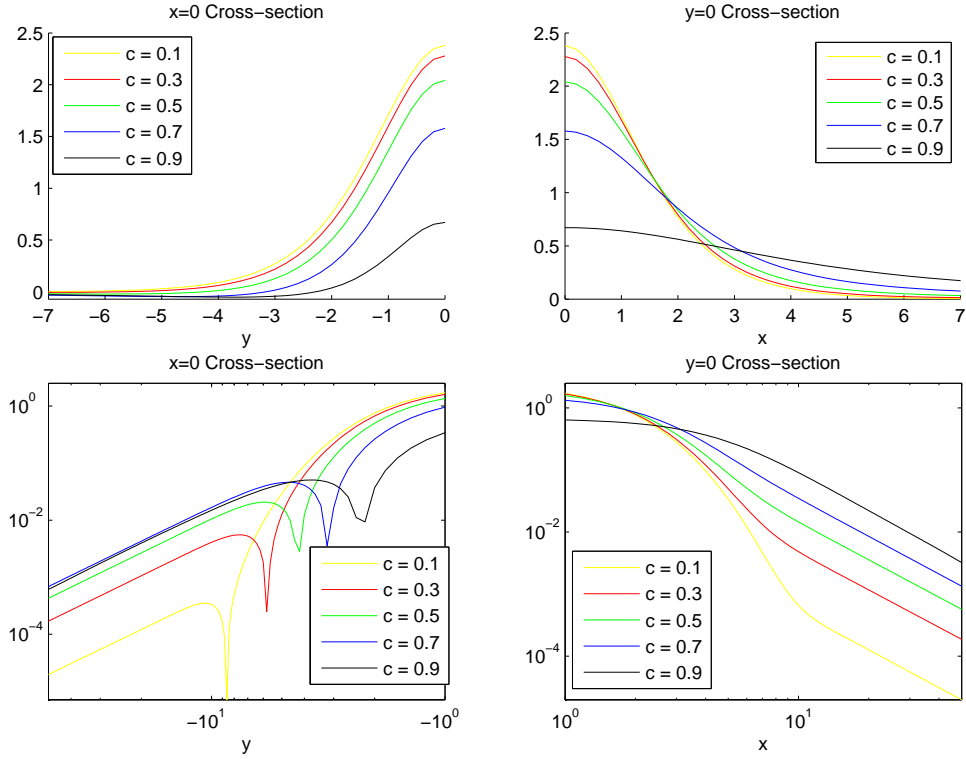

Figure 4: Cross-sections of the numerical solution for $\beta = 1$ and several c

First, two aspects of the solution for different combinations of c and β

$c = 0.3$
 $\beta = 1, 3, 5$ (top to bottom)

$\beta = 1$
 $c = 0.1, 0.5, 0.9$ (top to bottom)

Figure 5: Difference between the numerical solution v and best fit formulae v^* from [8]

are plotted on Figure 2. Both numerical solutions are computed on the domain $\Omega = [0, 25] \times [0, 25]$ with $h = 0.1$ and then extended symmetrically to $[-25, 25] \times [-25, 25]$. Only the essential part of the wave (near the center) is shown on these pictures. Top figures are level plots showing the waves from above and the bottom figures are three dimensional showing the structure of the wave in space.

We perform a detailed study of the numerical solution's shape with respect to main parameters – the relative dispersion $\beta = \beta_1/\beta_2$ and the velocity c . Figure 4 shows different aspects of the solution at $x = 0$ and $y = 0$ cross-sections. The parameter α is fixed as one ($\alpha = 1$) but parameters β and c vary. We apply the computational procedure with $L_x = L_y = 50$, $h = 0.2$, $\epsilon = 1.0e - 06$. On Figure 4, parameter $\beta = 1$ is held constant and the wave dependence on the phase velocity c for $c = 0.1, 0.3, 0.5, 0.7, 0.9$ is demonstrated. Linear plots of the solution are presented on the upper row while log-log plots of the absolute value of the solution are shown on the lower part. These types of plots help us to establish the size of the computational box.

One can observe that as the phase velocity c increases the wave's support along x direction increases too, but the maximum of the wave decreases. The linear part of the solution on the log-log plots is under the governance of the boundary function.

β	c	$\ v^* - v\ _\infty$	$\ v^* - v\ _2$
1	0.1	4.0554e-02	1.4802e-01
1	0.5	6.7063e-02	1.6766e-01
1	0.9	8.2821e-01	2.1671e0

Table 3: Differences between the numerical solution v and best-fit solution v^* from [8].

Figure 5 and Table 3 demonstrate the absolute value of the difference between the solution v^* by formulae [8] and the final solution of our procedure.

On the left side of Figure 5 the phase velocity $c = 0.3$ is fixed and β changes. On the right side the dispersion parameter $\beta = 1$ is kept constant while c changes. The experiments are done on a $[-50, 50] \times [-50, 50]$ domain but only the results near the zero point are plotted. For each of the examples

shown on Figure 5 more detailed estimate (using numbers) is given in Table 3. The difference is measured in the maximal and L_2 norms. One observes that for larger wave velocities c and dispersion parameters β the distinction becomes more pronounced. For example, for $\beta = 1$ and $c = 0.9$ the difference between the numerical solution obtained in this paper and the formulae v^* from [8] becomes ≈ 0.8 !

7. Conclusions. Fourth and sixth order finite difference schemes are applied for numerical evaluation of the stationary travelling wave solutions to the Boussinesq equation in this paper. The high accuracy of the method applied is demonstrated on several experiments. The numerical solution obtained here performs similarly to the numerical solutions given in [8, 9] with respect to solution shape and the dependence on the velocity c and relative dispersion β . The best-fit approximation formulae from [8] fail to satisfy the initial equation in the classical sense in the neighborhood of the origin. In the future, we will exploit the obtained stationary traveling wave solutions as initial data to the corresponding Boussinesq equation in order to seek two dimensional solitary wave solutions to (1).
